Abstract: Aspergillus infection usually happened in immunocompromised patients. Disseminated aspergillosis most commonly involves the lung, with the eye being the second most common site of infection. Aspergillus fumigatus and Aspergillus flavus are the species most frequently isolated from patients with intraocular infection. We present a rare case with chronic lymphocytic leukemia who suffered from endogenous Aspergillus endophthalmitis without any evidence of disseminated aspergillosis before this episode. The aspergillus endophthalmitis should be always considered in the immunocompromised patients even there are no symptoms or signs of systemic infection. Although rare, our case is an example of Aspergillus endophthalmitis to remind us that early diagnosis is the better way to improve outcome for these patients.
